Abstract. In this paper we discuss the prediction of timing properties of a multi-tasking component-based application already during the design phase. At this stage, it is of vital importance to guarantee that the timing requirements (e.g. response times) of a real-time application will be satisfied. This can be achieved by predicting the real-time behaviour of a component-based application. In this paper, we extend an existing scenario-based approach \cite{2} with the possibility to model the behaviour of an application and the behavior of the underlying components. This extension allows an application developer to predict the real-time properties of a component assembly before its actual implementation. The modelling involves the specification of synchronization constraints for tasks and the simulation of application behaviour. A concluding case-study of video encoder development reveals that the approach is not only feasible but also brings a contribution to the design of the software-intensive multimedia real-time systems.

1 Introduction

Software-intensive embedded systems usually have two closely coupled properties: limited resources and real-time constraints for execution of the applications. The limitation of resources, such as memory size, bus bandwidth and processing power, complicates the satisfaction of the real-time constraints. It is evident that these guarantees are of great importance for e.g. multimedia devices.

For high-volume embedded appliances, such as PDAs and mobile phones, etc, an open, component-based framework for a middleware layer in the software architecture has been proposed. This framework, known as Robocop \cite{3}, was used as a reference for specifying a follow-up ITEA research project, called Space4U. Our research aims at improving the Robocop component-based architecture, by enabling the predictions of application real-time properties.

During the design phase, an application is evaluated to fit on a target system. For an \textit{a-priori} evaluation, this requires prediction of the resource usage of an application. Early prediction of resource usage and timing properties of an application at the design stage increases system robustness and reduces cost and problems in product development.
Component-based technology complicates the prediction of resource usage and timing properties of an application. In component-based systems, the actual behaviour and resource usage are determined by an ensemble of internally and also externally developed components. Thus, the prediction task becomes twofold: (1) find and express the component’s extra-functional properties, and (2) combine these properties to predict the behaviour of the composition of the constituent components. In the sequel, we will denote an application also as an assembly, because it makes use of the underlying components.

The challenge of predicting real-time properties of a component assembly is of significant interest because of the rapid development of component-based technologies in the embedded systems domain. Some approaches represent an engineering practice [7-9] to the problem. We used [8] as a guideline for our work. A very promising technique that allows design-time estimations of real-time properties of component-based systems is presented in [10]. In this technique, many possible types of software constructions are taken into account, like synchronous and asynchronous communication, as well as synchronization constraints. Recent work on the prediction of performance for evolving architectures is described in [11]. This approach is based on collecting the component performance data on different platforms and interpolating it for new components or platforms. Real-time frameworks have been introduced in the object-oriented development field. Methods have emerged that enable execution of UML-like specifications, notably Room [12] and Rhapsody [13]. The PRIMA-UML methodology [14] applies queuing networks and extends UML with a real-time performance model for system performance validation. We concentrate on similar methods, but now in the component-based development field. The scenario-based approach proposed in [15] involves estimating static resource usage of a component assembly.

In contrast with this, through our scenario simulation approach, we address a dynamic or time dependent instead of static resource usage, thereby giving more accuracy in the prediction of the assembly behaviour. With respect to task synchronization, we adopt the use of synchronization constraints (precedence, critical sections, mutexes) for further adding accuracy in the prediction. The approach still requires little effort from an application developer, because the introduction of application scenarios narrows the state-space and behaviour of an application that the developer should model and simulate. A practical case-study revealed that, besides proving feasibility, the important problem of task parallel execution and synchronization comes to the foreground. This prevents that these usually hidden problems remain unsolved.

The paper is structured as follows. Section 2 addresses various aspects of timing properties of a component assembly. Section 3 presents the Robocop component model, as a fundament for the new extensions. Section 4 discusses the workflow of the approach and gives specifications of the required models. Section 5 clarifies the proposed approach with an encoder application case-study. Section 6 concludes with the benefits and disadvantages of the proposed prediction-enabling technique.
2 Timing and Parallel Execution Aspects

This section defines basic terms used in the paper, e.g. timing property, task and task synchronization constraints. There is a clear difference between the component and application timing properties. The component timing properties are independent from system run-time execution and scheduling. In most of the cases, these properties are: worst-case, mean-case and best-case execution times per operation. The application timing properties, instead, are closely coupled to run-time instances, tasks and scheduling algorithms used in the system. In the real-time application domain, we concentrate on the following timing properties: response and blocking times of a task as well as the number of missed deadlines of a task.

The response time of a task is not just a sum of execution times of the operations comprising the task. Usually, the response time is composed of the execution time, blocking time and pre-emption time of the task. Therefore, for the assembly timing property, the task synchronization and scheduling aspects should be considered.

In literature, several definitions of tasks are used. In our context, the task is an event-triggered sequence of executed operations. The operations composing a sequence may be implemented by different services. The operations within the sequence may be called synchronous or asynchronous. The tasks may have synchronization constraints between them, e.g. precedence, rendezvous and mutual exclusion. Usually, the system resource sharing imposes the synchronization constraints.

All of the above aspects have been used in this paper in a regular way, confining to the presented definitions.

3 Robocop Component Model

The Robocop component model is inspired by existing component-based architectures, such as COM [4], CORBA [5], and Koala [6]. A Robocop component is a set \( M \) of possibly related models, as depicted in Fig. 1.

![Fig. 1. Example Robocop component model](image)

Each individual model \( m \) provides a particular type of information about the component. Models can be represented in readable form (e.g. documentation)
or in binary code. One of the models is the *executable model* that contains the executable component. Other examples are: *resource model*, *functional model*, and *behaviour model*.

A component offers functionality through a set of ‘services’ \( P \) (see Fig. 2 and Fig. 3(a)). Services are static entities, which are the Robocop equivalents of *public classes* in object-oriented (OO) programming. More formally, we can specify an arbitrary executable model \( m \) by:

\[
m = P, \quad \text{where } m \text{ is an Executable Model and } P \text{ is a set of } p \text{ (services)}.\]

**Fig. 2.** Specification of executable model

Services are instantiated at run-time, using a service manager. The resulting entity is called ‘service instance’, which is a Robocop equivalent of an *object* in OO programming. A Robocop service may define several interfaces (ports). We distinguish a set of ‘provides’ ports \( PR \) and a set of ‘requires’ ports \( REQ \). The former defines interfaces that are offered by the service, while the latter defines interfaces that the service needs from other services in order to operate properly. An interface is defined as a set of implemented operations \( \text{impl_opr} \). A service \( p \) being part of the above-mentioned executable model is specified in Fig. 3(b).

**Fig. 3.** (a) Example of executable component, (b) Specification of Robocop service

Please note that a *Robocop service* is equivalent to a *component* in COM or CORBA, i.e. a service is a subject of composition, and it has input and output ports. A *Robocop component* is a deployable container that packages these services. Therefore, in the Robocop context, the term *composition* stands for a composition of services.
The Robocop architecture implies no implementation-level constraints. A service can implement any number of threads. Besides this, synchronous and asynchronous communication types are possible.

4 Scenario Simulation Approach

4.1 Workflow of the Approach

The main task of a component-based application developer is, given a set of available components and requirements for an application, to select the right components and compose them into an application that will satisfy the given requirements.

![Conceptual view on the prediction-enabling composition workflow](image)

Fig. 4. Conceptual view on the prediction-enabling composition workflow

In the domain of real-time application, a developer needs to focus on satisfying extra-functional requirements like response time, or memory usage (Fig. 4). The proposed prediction-enabling composition workflow contains principal steps for a real-time application developer. These steps lead a developer from the application requirements and set of available components to an application with the required timing properties. The timing properties are obtained already in the design phase, prior to running the assembly on the target system. The workflow is based on the two following assumptions.

1. Resource usage property and behaviour of the constituent components are specified and available in the corresponding component models.
2. An application developer is able to find out critical scenarios of the application.

The main steps of the workflow are depicted in Fig. 5. The remainder of this section defines the consecutive steps of the workflow.

**Component composition.** A developer selects and composes a set of available components into an application. According to the above assumption (1), selected components should be real-time aware, e.g. have both a resource model and a behaviour model. These two models are to be written by a component developer and used to accompany an application scenario model that is constructed in the next step and, thus, complete the mosaic of the application behaviour. The description of the models is given in Section 4.2.

Construction of application scenario model. For each critical or commonly used scenario, a developer constructs (with the help of a GUI-based tool) an application scenario model (see Fig. 5). The application scenario model consists of two parts: (a) description of service instances and bindings between them, particular for the selected scenario, and (b) description of the application-level events and active threads that trigger execution of operations of the service instances.

Compilation of models. The application scenario, component resource and component behaviour models are jointly compiled. The goal of the compilation is to reconstruct (generate) the tasks running in the application. Prior to compilation, the task-related data is spread over different models. For instance, the task periodicity may be specified in an application scenario model, whereas the operation call sequence comprising the task is specified in relevant component behaviour models. The compiler reconstructs all necessary properties of the tasks, like deadline, period, priority and operation call sequence.

Simulation of tasks execution. An application developer applies a scheduler to the reconstructed task pool, simulating the execution of defined scenario. The scheduling algorithm may vary depending on the algorithm of the operating system, on which the application is supposed to execute. The scheduler should implement prevention of unbounded priority inversion, because the models define various types of synchronization constraints. Resulting data from the scheduler is the task execution timeline. This timeline is a subject for schedulability and performance analysis.
Schedulability analysis. The analysis of the task execution timeline helps to reason about application timing properties like response time, latency of critical tasks, overall schedulability and processor utilization bounds. Many other possible application properties can be derived: rate of missed deadlines, blocking time, worst and best-case response time per task. This step results in predicted real-time and performance properties of the designed application.

Checking properties against requirements. The predicted timing properties are checked against the real-time requirements of an application (see Fig. 5). For example, worst-case response time of a critical task is verified with its deadline specified in the requirements. If any of the requirements are not met, a developer optimises the composition and repeats the workflow.

4.2 Model Description

The purpose of this section is to specify the models introduced in the previous section. It is emphasized here that the models are not a goal by themselves, but are required for obtaining the resource consumption and timing properties. The following sub-sections specify the above-mentioned models in detail.

Component Resource Model. The component resource model \( RM \) is one of the models of the Robocop component model. \( RM \) specifies the predicted resource usage for all the operations \( impl\_opr \) implemented by services of an executable component. Resources \((r)\) can be memory, CPU, etc. The predicted resource usage is specified as a \((\text{claim}, \text{release})\) tuple for non-processing resources, like memory. For processing resources, like the CPU, the usage is specified as a single \( \text{claim} \) in milliseconds.

\[
m = RM,
\]

where \( m \) is a Resource Model and \( RM \) is a set of \( rm \) (resource usage of an operation).

\[
rm = (impl\_opr, resource, consumption),
\]

for operation \( impl\_opr \).

\[
resource = r \{\text{memor, cpu, bus, ...}\}.
\]

\[
consumption = \text{claim},
\]

in case resource is cpu.

\[
consumption = (\text{claim}, \text{release}),
\]

in case resource is memory.

\[
consumption = (\text{claim}, \text{time}),
\]

in case resource is bus.

A component developer defines the resource usage properties of an operation by worst-case analysis. These properties are calculated only for the operation body itself, excluding resource usage properties of called operations. This approach allows calculating resource usage of any sequences of operation calls. In
this paper, we do not address platform and parametric variations of the operation resource usage. The resource model should be specified for a particular reference platform.

**Component Behaviour Model.** The component behaviour model (BM) also belongs to the Robocop component model. BM specifies the behaviour of all operations impl_opr implemented by services of an executable component. A semi-formal specification of the model is as follows.

\[
m = \text{BM, where } m \text{ is a Behaviour Model and } \text{BM} \text{ is a set of } bm \text{ (behaviour of an operation).}
\]

\[
bm = (\text{impl_opr, mutexed, behaviour, } T),
\]

\[
\text{where } \text{impl_opr} \text{ is the implemented operation and } \text{behaviour} \text{ is the operation behaviour description, } T \text{ is a set of } t \text{ (task triggers the operation is associated with), }
\]

\[
\text{mutexed} \text{ shows if the operation is mutexed.}
\]

\[
\text{behaviour} = (\text{called_opr}_1, \text{called_opr}_2, \ldots \text{called_opr}_n, \text{CS}),
\]

\[
\text{where } \text{called_opr}_1, \ldots \text{called_opr}_n \text{ is a sequence of called operations and } \text{CS} \text{ is a set of } cs \text{ (critical sections).}
\]

\[
called_opr = (opr, nmb\_iterations, calling\_type),
\]

\[
\text{where } opr \text{ is the called operation and } nmb\_iterations \text{ - number of times the operation is called,}
\]

\[
calling\_type \{ \text{synch, asynch} \},
\]

\[
\text{cs} = (\text{called_opr}_1, \text{called_opr}_2, \ldots \text{called_opr}_n),
\]

\[
t = (\text{periodicity, param, PRECED}),
\]

\[
\text{where } \text{periodicity} \{ \text{periodic, sporadic, aperiodic} \}, \text{PRECED} \text{ is a set of } \text{preced} \text{ (preceding task triggers),}
\]

\[
\text{param} \text{ includes various parameters of } t,
\]

\[
\text{preced} = (t, \text{ratio}),
\]

\[
\text{where } t \text{ is a task trigger that precedes the specified task trigger.}
\]

\[
\text{ratio} = \text{nmb\_jobs\_of\_current\_task} / \text{nmb\_jobs\_of\_preceding\_task}.
\]

**Fig. 7.** Specification of component behaviour model

Firstly, for each operation impl_opr implemented by an executable component, a component developer defines its mutual exclusion property. If an operation is mutexed, at most one thread can enter the operation at the same time. Secondly, operation behaviour describes a sequence of operation calls to other interfaces made inside the implemented operation. For example in Fig. 8, the implemented operation Decoder.decode() has a behaviour described by the following call sequence: IGetElement.getFrame(), IStoreElement.storeFrame(). The IGetElement and IStoreElement are the interfaces provided by ReadBuffer and WriteBuffer services, respectively.

For each called operation called_opr in the sequence, the number of iterations nmb_iterations and calling type calling_type are specified. Additionally, a set of critical sections CS can be specified if necessary in behaviour. Critical section cs
Fig. 8. Sequence of operation calls (behaviour) of decode() operation

points out the operation of which the execution cannot be pre-empted. Please
note that each called_opr should belong to one of the required interfaces for the
service.

Finally, a component developer should define the operation autonomous
behaviour $T$. We consider that an operation has autonomous behaviour if there is
at least one task trigger $t$ implemented by the operation. One of the examples
of the task trigger is an iterative thread, triggered periodically by a timer. In
the decoder example, the decode() operation can implement an iterative thread,
which is triggered by the system timer each 20 ms. Thus, the whole calling se-
quence repeats each 20 ms. In the model, the task trigger properties can be
specified, including periodicity, period, deadline, offset, precedence constraints
preced, etc.

Concluding, these two models describe component resource usage and be-
aviour properties independent of the application context where the component
is going to be used.

**Application Scenario Model.** According to Fig. 5, we propose to model
scenarios in an application. This allows decomposing each type of application
behaviour into a separate simple scenario model. Thus, we can reduce the com-
plexity of the complete behavioural model of the application and partly avoid
exploration of all application states.

The application scenario model ($SM$) specifies application structure and be-
aviour for a critical or commonly used execution scenario. Several SMs can
be built for an application, depending on a number of interesting scenarios.
An application developer is in charge of the scenario models construction. The
semi-formal structure of the model is presented below (Fig. 9).

Firstly, an application developer specifies an application structure for a sce-
nario. The structure is represented by a tuple containing $SI$ (set of service in-
stances $si$) and $B$ (set of bindings between the $si$). A binding includes information
about the bound service instances from, and to, and in/out ports of the instances
from port, to port. In Fig. 10, dashed lines represent the bindings.

Secondly, the model defines the components (depend) used in the application.
This data links the scenario model with the behaviour and resource models of
the corresponding components.

Finally, the application scenario model specifies sets $E$ and $T$ of events $e$ and
in-application task triggers $t$, respectively. We define an event as any influence
Fig. 9. Specification of application scenario model

coming from outside to an application that changes the current application state. Hardware interrupt, timer or signal from an external sensor can trigger the event. Normally, this influence is expressed as a call of one of the operations of the application component.

Conceptually, an in-application task trigger is also an event, but it comes from inside the application. In other words, this task trigger is implemented by the application developer. Please recall that we also have a task trigger notion in the component behavior model. That task trigger differs by being implemented inside a component. The two types of task triggers are separated into different models, because an in-component task trigger should be specified by a component developer and an in-application task trigger should be specified by an application developer.
The application task trigger calls one of the operations of the application components, thereby starting the task action sequence. Therefore, the $e$ and $t$ must be associated with the operation called first ($opr$). In Fig. 11, an application periodic task trigger calls decode() operation each 40 ms. Thus, in the scenario model the trigger should be associated with this operation.

For each event $e$ and in-application task trigger $t$, its periodicity, parameters $param$ and precedence constraints $preced$ can be specified.

![Fig. 11. Task triggered by in-application trigger](image)

When the scenario models are ready, a developer proceeds to the next phase.

4.3 Model Compilation and Schedulability Analysis

In the Space4U project, we have developed a Robocop Integration Environment (RIE) tool that does compilation of the above-mentioned models, simulation of an application scenario and visualization of the simulation data.

In the model compilation phase, an application developer brings together the application scenario model, behaviour and resource models of the components deployed in the application. At this stage, this set of models can be compiled by the RIE. The conceptual goal of the compilation is to identify and reconstruct a set of tasks that the application will execute for a particular scenario.

The task-set reconstruction uses only the data from the three above-mentioned models. These models contain all events; in-application and in-component task triggers, as well as operation call sequences that define a flow of control for the tasks.

For the decoder example, the task reconstruction works as follows: the related behaviour model specifies the operation call sequence of the operation decode(): getFrame(), storeFrame() (see Fig. 8). Afterwards, the compiler gathers from related behaviour models the behaviour of these two operations. The operation getFrame() calls one operation belonging to other interfaces: ILogData.logEvent() (see Fig. 12).

If an operation has an empty operation call sequence (does not call operations belonging to other interfaces), it is considered as a leaf and the task generation proceeds to the next branch. Let us assume that operation ILogData.logEvent() is such a leaf. The next operation storeFrame() then also calls this leaf operation: ILogData.logEvent() (see Fig. 8). Thus, the complete reconstructed sequence of the operations executed in the task is as depicted in Fig. 13.
A resource-usage property of each operation in this sequence is specified in the claim primitive in the related component resource model (see Section 4.2). Knowing this data, we can calculate total resource usage of the task. For example, the CPU time used by the task (execution time) is the sum of CPU times used by the operations composing the task. In Fig. 13, the total execution time of the task amounts to: 8ms + 5ms + 2ms + 5ms + 2ms = 22ms. The other task parameters (period, offset, and deadline) and precedence are obtained from the associated task trigger properties that are specified in models of the previous section.

Synchronization constraints for each task are also extracted from the models. The task precedence has been already mentioned. Mutexed and critical section cs, which are properties of an operation, as well as a task precedence preceded specified in the component behaviour model, all define synchronization constraints of tasks.

An execution of the reconstructed tasks of the scenario is simulated by a virtual scheduler. During the simulation, these synchronization constraints are taken into account. The scheduling algorithm should be the same as an algorithm of the targeting operating system. The simulation results are represented as a task execution timeline (see Fig. 14).

The schedulability analysis of the simulation data leads to the timing properties of an application. The response time, blocking time, number of missed deadlines can be found for each task. Besides this, the processor utilization bound can be analyzed per task. The predicted properties can be validated against the application requirements.
5 Video Encoder Case-study

The objectives of the video encoder case-study are to show practical aspects of the approach utilization and give further clarification. The example starts with requirements, goes through the prediction-enabling composition workflow and ends with predicted timing properties of the application.

5.1 Requirements

Taking into account that we do not focus on functional requirements, the required functionality can be expressed in one sentence: *the application shall encode on-the-fly the audio and video signals in MPEG-4 format and subsequently multiplex the compressed signals into one stream* (REQ1). The extra-functional requirement for the TV-like application: *the number of skipped frames during the encoding on-the-fly should be NULL* (REQ2). This implies that we do not allow missed deadlines for audio and video encoding tasks (real-time application).

5.2 Component Selection

After the requirements elicitation, the process of the component-based application development continues with component selection. Because our application has a real-time nature, we should select only real-time aware components (resource and behaviour models in their distribution package).
We selected two real-time aware components that bring the required functionality: MPEG4 Encoder and DataBroker having three service each as indicated in Fig. 15. Each service has provides and requires interfaces. For instance, the VideoEnc service provides IVideoEnc interface and requires IBufferAccess and IMux interfaces. The IVideoEnc interface encapsulates the VideoEncode() operation. All public operations are also represented in Fig. 15.

The corresponding resource and behaviour models (see Fig. 16) are constructed according to the rules defined in Section 4.2. The behaviour (resource) model specifies behavioural (resource usage) aspects of all public operations of the component. Note that there are no task-triggering operations specified in services of both components (fields for task triggers \( T \) are empty). It means that all operations are passive (have no autonomous behaviour) and should be controlled by application-level events and task triggers.

![Component Resource Model](image)

**Fig. 16.** Behaviour and resource models of the components from Fig. 15

### 5.3 Composing the Encoder Application

The design (composition) phase, which is the first stage of the workflow, consists of three steps: service instantiation, service instances binding and design of application level events and task triggers.

The **service instantiation** is basically a process of defining a structure of an application depending on required functionality. Our encoder should read, encode AV streams and multiplex them in one MPEG-4 stream. Finally, this stream should be stored. Therefore, the encoder should have at least the following service instances: audio-, video-readers, audio-, video-encoders, multiplexer, and writer. Data communication between the instances can be realized by a set
of buffers. This structure (service instantiation) is depicted in Fig. 17. As can be noticed, the Reader service is instantiated twice (aReader, vReader) and the Buffer service has three instances (vBuffer, aBuffer, mBuffer).

The second step is binding the service instances. Requires interfaces are connected to provides interfaces of the same type, thus defining data and control flows in the application. Fig. 17 depicts the service instance bindings by the connecting arrows.

![Fig. 17. Binding the encoder service instances](image)

In the third step, a developer identifies necessary application-level events and task triggers. In component-based systems, an application-level task trigger can be implemented in the code of application as a separate thread that wakes up periodically (by timer signals) and invokes one of the component operations. In its turn, an event is usually implied by hardware platforms (i.e., interrupts). A developer needs not to implement events, but should take them into account during the design phase.

The services composing the encoder application have no autonomous operations with task triggers inside (all services are passive). In order to make the application alive, we designed six task triggers executing on the application level (see Fig. 18). Each of the task triggers periodically invokes one of the operations, thereby creating a separate thread of control. For example, Trigger1 invokes the IRead.readFrame() operation of the vReader service instance. This operation reads one video frame from a file and stores the frame in vBuffer. All triggers are designed to fire with periodicity of 40 ms, since this is common video streaming rate. We defined the deadlines for the triggered tasks to be equal to their periods (40 ms). We specified no precedence constraints for the tasks. Having this information we can construct an application scenario model.

### 5.4 Constructing the Application Scenario Model

The construction of a scenario model starts with identification of relevant scenarios. The relevant scenario can be either a common execution scenario or a critical scenario. In the encoder case, the common execution scenario (e.g., en-
coding mode) is relevant to consider, because it implies high resource usage and correlates with REQ2 (see Section 5.1).

5.5 Models Compilation

The RIE compiler reconstructs the tasks in the application scenario (reconstruction process is explained in Section 4.3). Here we graphically represent the result of the task reconstruction (see Fig. 20). The tasks are circular lines with arrows
showing the control flow directions. For example, video encoding task is triggered by Trigger3 who calls operation VideoEncode(). This operation first calls getFrame() operation of vBuffer, then encodes the received frame and finally calls putVFrame() operation of Mux service instance. This task repeats each 40 ms. The sequence diagram for the task is similar to the structure from Fig. 11.

Fig. 20. Reconstructed tasks after models compilation

5.6 Simulation of Tasks Execution

An execution of the reconstructed tasks can be further simulated by the RIE scheduler. The current algorithm used in the RIE scheduler is rate monotonic with bounded priority inversion. The virtual scheduling of the encoder tasks results in the execution timeline depicted in Fig. 21. The three bold vertical lines show: completion, deadlines and triggering moments of each task instance.

Fig. 21. Part of the task execution timeline for encoder application
5.7 Schedulability Analysis

The schedulability analysis leads to the requirements validation. Our extran
tional REQ2 demands no missing deadlines of the audio and video encoding
tasks (see Section 5.1). According to the generated tasks execution timeline
(Fig. 21), video encoding (TaskID = 3) and audio encoding (TaskID = 4) tasks
meet all deadlines for a simulation period of 10 seconds. Note that this is only
true under the condition that the assigned CPU budget is 100%.

This step ends with the conclusion that the designed application meets its
real-time requirements and we can now proceed to the implementation phase.

6 Conclusions

We have extended the scenario-based approach for predicting resource usage of
component based systems in [2] with the specifications of task synchronization,
component behaviour model and application scenario model. This allows simul-
ation of the real-time task execution per application scenario and handling of
synchronization constraints. Based on the simulation results, a developer can
derive the behaviour and dynamic resource consumption of an application per
scenario. Afterwards, a developer uses this data for prediction of the real-time
properties of an application. The method was validated through the Robocop
Integration Environment tool that automates complex operations and guides a
developer through the composition process.

The proposed prediction approach has a number of benefits. Firstly, it is
general and can be applied in different application domains and for various
architectural styles. For example, it works for ‘blackboard’ and ‘client-server’
architectures. Secondly, the approach allows prediction of dynamically chang-
ing resource usage. Thirdly, the approach is more accurate by incorporating
task synchronization constraints and distinguishing synchronous and asynchro-
nous communication. Fourthly, the method is compositional, meaning that the
resource-usage data of an application can be based on data from its constituent
components. Finally, the use of scenarios decreases modelling complexity.

The proposal also has some assumptions and limitations that need further
study. Firstly, it assumes that resource usage is constant per operation, whereas
it actually may depend on parameter values passed to operations and/or ap-
lication state. Secondly, the method is restricted to the Robocop component
model, which has a notion of ‘requires interfaces’, whereas other architectures
such as COM, do not have this notion. Finally, it provides no techniques for
specifying the component resource model for different platforms. Extending the
relatively simple case in this paper, we are currently validating the approach on
a more complex MPEG-4 codec software.
